Preface

Public health surveillance involves the systematic collection, analysis and dissemination of data regarding adverse health conditions. The data are used to monitor trends and identify outbreaks in order to assess risk factors, target disease control activities, establish resource allocation priorities and provide feedback to the medical community and the public. These data support public health interventions for both naturally occurring and intentional spread of disease.

Statistics incorporated into tables, graphs and maps reflect data reported from health care providers who care for Mississippi residents. Cases counted have met the surveillance case definitions of the CDC and the Council of State and Territorial Epidemiologists (CSTE). Unless otherwise noted all rates are per 100,000 population. Data are based on “event” date of the case with the exception of TB in which the case confirmation date is used. The “event” date is defined as the earliest known date concerning a case and is hierarchical (onset, diagnosis, laboratory date or date of report to the health department).

Mississippi law (Section 41-3-17, Mississippi Code of 1972 as amended) authorizes the Mississippi State Board of Health, under which the Mississippi State Department of Health (MSDH) operates, to establish a list of diseases which are reportable. The reportable disease list and the Rules and Regulations Governing Reportable Diseases and Conditions may be found online at http://www.msdh.state.ms.us/msdhsite/_static/14,0,194.html. Class 1 diseases, reportable by telephone at first knowledge or suspicion, are those to which the MSDH responds immediately to an individual case; Class 2 diseases, those reportable within a week of diagnosis, and Class 3 diseases, reportable only by laboratories; do not necessitate an immediate response to an individual case.

To report a case of any reportable disease or any outbreak, please call 601-576-7725 during working hours in the Jackson area, or 1-800-556-0003 outside the Jackson area. For reporting tuberculosis, you also may call 601-576-7700, and for reporting STD’s or HIV/AIDS, you may call 601-576-7723. For emergency consultation or reporting Class 1 diseases or outbreaks nights and weekends please call 601-576-7400.

The data included in the following document have come from physicians, nurses, clinical laboratory directors, office workers and other health care providers across the state who called or sent in reports. Without these individuals, public health surveillance and response would be incapacitated. For your dedication to this important part of public health information, we thank you.

# Reportable Disease List

**Mississippi State Department of Health**  
**List of Reportable Diseases and Conditions**  
**Reporting Hotline:** 1-800-556-0003  
**Monday - Friday, 8:00 am - 5:00 pm**  
**To report inside Jackson telephone area or for consultative services**  
**Monday - Friday, 8:00 am - 5:00 pm:** (601) 576-7725  
**Phone**  
**Fax**  
- Epidemiology: (601) 576-7725  
  (601) 576-7497  
- STD/HIV: (601) 576-7723  
  (601) 576-7909  
- TB: (601) 576-7700  
  (601) 576-7520  

Class 1 Conditions may be reported nights, weekends and holidays by calling: (601) 576-7400

Class 1: Diseases of major public health importance which shall be reported directly to the Mississippi State Department of Health (MSDH) by telephone within 24 hours of first knowledge or suspicion. Class 1 diseases and conditions are dictated by requiring an immediate public health response. Laboratory directors have an obligation to report laboratory findings for selected diseases (refer to Appendix B of the Rules and Regulations Governing Reportable Diseases and Conditions).

## Any Suspected Outbreak (including foodborne and waterborne outbreaks)

Class 4: Diseases of public health importance for which immediate reporting is not necessary for surveillance or control efforts. Diseases and conditions in this category shall be reported to the Mississippi Cancer Registry within six months of the date of first contact for the reportable condition.

The National Program of Cancer Registries at the Centers for Disease Control and Prevention requires the collection of certain diseases and conditions. A comprehensive reportable list including ICD9CM codes is available on the Mississippi Cancer Registry website, http://mcr.umc.edu/documents/ReportableCases10-09andlater.pdf.

Each record shall provide a minimum set of data items which meets the uniform standards required by the National Program of Cancer Registries and documented in the North American Association of Central Cancer Registries (NAACCR).
Arboviral Infections (mosquito-borne)

Background
Arthropod-borne viral (arboviral) diseases in Mississippi are limited to a few types transmitted by mosquitoes. In this state, there are four main types of arboviral infections that have been reported: West Nile virus (WNV), St. Louis encephalitis (SLE), eastern equine encephalitis (EEE), and LaCrosse encephalitis (LAC). WNV and SLE are members of the Flavivirus genus, while EEE is an Alphavirus, and LAC is in the California virus group of Bunyaviruses.

Infections do not always result in clinical disease. When illness occurs, symptoms can range from a mild febrile illness to more severe cases of neuroinvasive disease with symptoms of encephalitis and/or meningitis. Neuroinvasive disease can result in long term residual neurological deficits or death. The proportion of infected persons who develop symptoms depends largely on the age of the persons and the particular virus involved.

Mosquito borne arboviral infections are typically more common in the warmer months when mosquitoes are most active, but WNV cases have been reported year round. All are transmitted by the bite of an infected mosquito, but the mosquito vectors and their habitats differ. Infections are not transmitted by contact with an infected animal or other person; humans and horses are “dead end” or incidental hosts. Rare instances of WNV transmission have occurred transplacentally and through transplanted organs and blood transfusions.

Methods of Control
The methods of controlling mosquito-borne infections are essentially the same for all the individual diseases. The best preventive strategy is to avoid contact with mosquitoes. Reduce time spent outdoors, particularly in early morning and early evening hours when mosquitoes are most active; wear light-colored long pants and long-sleeved shirts; and apply mosquito repellent to exposed skin areas. Reduce mosquito breeding areas around the home and workplace by eliminating standing or stagnant water. Larvacides are effective when water cannot easily be drained.

Mosquito Surveillance
Mosquitoes are collected throughout the state for West Nile and other arboviral testing to provide information regarding the burden and geographic distribution of infected vectors. Mosquitoes are collected by local mosquito programs and MSDH personnel and submitted as pools of 5-50 mosquitoes for testing. In 2010, 439 mosquito pools were submitted to the MSDH Public Health Laboratory (PHL) for WNV, SLE, and EEE testing.
**Arboviral Testing**

The MSDH PHL performs an arboviral panel consisting of IgM testing for WNV and SLE, and, for patients less than 25 years of age, LAC IgM. Clinicians are encouraged to call MSDH Epidemiology or the PHL for specifics and indications for arboviral testing. 732 samples were submitted to the MSDH PHL for arboviral testing in 2010.

Please refer to the individual disease summaries for information on and epidemiology of each specific arbovirus.

---

### Eastern Equine Encephalitis (EEE)

<table>
<thead>
<tr>

<td>0.0</td>
</tr>
<tr>
<td>2009 Case Total</td>
<td>0</td>
<td>0.0</td>
<td>0</td>
<td>0.0</td>
</tr>
</tbody>
</table>

**Clinical Features**

Clinical illness is associated with symptoms that can range from a mild flu-like illness (fever, headache, muscle aches) to seizures and encephalitis progressing to coma and death. The case fatality rate is 30-50%. Fifty percent of those persons who recover from severe illness will have permanent mild to severe neurological damage. Disease is more common in young children and in persons over the age of 55.

**Infectious Agent**

Eastern equine encephalitis virus, a member of the genus Alphavirus.

**Reservoir**

Maintained in a bird-mosquito cycle. Humans and horses are incidental hosts.

**Transmission**

Through the bite of an infected mosquito, usually Coquilletidia perturbans. This mosquito, known as the salt and pepper or freshwater marsh mosquito, breeds mainly in marshy areas.

**Incubation**

3-10 days (generally within 7 days).

**Reporting Classification**

Class 1.
**Epidemiology and Trends**

Human cases are relatively infrequent largely because primary transmission takes place in and around marshy areas where human populations are generally limited. There were no reported cases of EEE in Mississippi in 2010. The last two reported cases of EEE occurred in October 2002.

Horses also become ill with EEE and are dead end hosts. Infected horses can serve as sentinels for the presence of EEE, and can indicate an increased risk to humans. The Mississippi Board of Animal Health reports equine infections to MSDH, and in 2010, 19 horses tested positive for EEE. The EEE-positive horses were located in the southern part of the state with 89% of the horses reported from District IX and District VIII. Reports were also received from Pike (1) and Scott (1) counties. There were no reported EEE positive mosquito pools in 2010.

### LaCrosse Encephalitis

<table>
<thead>
<tr>
<th></th>
<th>2010 Case Total</th>
<th>2010 rate/100,000</th>
<th>2009 Case Total</th>
<th>2009 rate/100,000</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>0</td>
<td>0.0</td>
<td>0</td>
<td>0.0</td>
</tr>
</tbody>
</table>

### Clinical Features

Clinical illness occurs in about 15% of infections. Initial symptoms of LaCrosse encephalitis infection include fever, headache, nausea, vomiting and lethargy. More severe symptoms usually occur in children under 16 and include seizures, coma, and paralysis. The case fatality rate for clinical cases of LaCrosse encephalitis is about 1%.

### Infectious Agent

LaCrosse encephalitis virus, in the California serogroup of *Bunyaviruses*.

### Reservoir

Chipmunks and squirrels.

### Transmission

Through the bite of an infected *Ochlerotatus triseriatus* mosquito (commonly known as the tree-hole mosquito). This mosquito is commonly associated with tree holes and most transmission tends to occur in rural wooded areas. However, this species will also breed in standing water in containers or tires around the home.

### Incubation

7-14 days.
**Reporting Classification**
Class 1.

**Epidemiology and Trends**
Reported LaCrosse encephalitis remains relatively rare in Mississippi, with 15 reported cases since 1999. There were no reported cases of LaCrosse encephalitis in 2010.

Of the 15 total cases since 1999, 53% were in females. The ages ranged from 3 months to 78 years of age, with 93% of the cases being under the age of 15.

Another Bunyavirus in the California group, Jamestown Canyon encephalitis virus, has also been seen in Mississippi, with one reported case in 1993, one in 2006, and one in 2008. There were no reported cases of Jamestown Canyon encephalitis virus in 2010.

**St. Louis Encephalitis**

<table>
<thead>
<tr>
<th>2010 Case Total</th>
<th>2010 rate/100,000</th>
<th>2009 Case Total</th>
<th>2009 rate/100,000</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>0.0</td>
<td>2</td>
<td>0.1</td>
</tr>
</tbody>
</table>

**Clinical Features**
Less than 1% of infections result in clinical illness. Individuals with mild illness often have only a headache and fever. The more severe illness, meningoencephalitis, is marked by headache, high fever, neck stiffness, stupor, disorientation, coma, tremors, occasional convulsions (especially in infants) and spastic (but rarely flaccid) paralysis. The mortality rate from St. Louis encephalitis (SLE) ranges from 5 to 30%, with higher rates among the elderly.

**Infectious Agent**
St. Louis encephalitis virus, a member of the genus *Flavivirus*.

**Reservoir**
Maintained in a bird-mosquito cycle. Infection does not cause a high mortality in birds.

**Transmission**
Through the bite of an infected mosquito generally belonging to genus *Culex* (*Culex quinquefasciatus, Culex pipiens*), the southern house mosquito. This mosquito breeds in standing water high in organic materials, such as containers and septic ditches near homes.
Incubation
5-15 days.

Reporting Classification
Class 1.

Epidemiology and Trends
The number of reported SLE cases fluctuates annually. There were no cases reported in 2004, 2006, 2008 or 2010, but there were nine cases with one death reported in 2005, two reported cases in both 2007 and 2009. There were no deaths due to SLE in 2007 or 2009.

Mississippi had no reported cases of SLE in 2010. No positive SLE mosquito pools were reported in 2010.

<table>
<thead>
<tr>
<th>West Nile Virus</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>2010 Case Total</strong></td>
</tr>
<tr>
<td><strong>2009 Case Total</strong></td>
</tr>
</tbody>
</table>

Clinical Features
Clinical illness occurs in approximately 20% of infected individuals. Most with clinical manifestations will develop the milder West Nile fever, which includes fever, headache, fatigue, and sometimes a transient rash. About 1 in 150 infected persons develop more severe West Nile neuroinvasive disease ranging from symptoms compatible with meningitis to encephalitis. Encephalitis is the most common form of severe illness and is usually associated with altered consciousness that may progress to coma. Focal neurological deficits and movement disorders may also occur. West Nile poliomyelitis, a flaccid paralysis syndrome, is seen less frequently. The elderly and immunocompromised are at highest risk of severe disease.

Infectious Agent
West Nile virus, a member of the genus *Flavivirus*.

Reservoir
WNV is maintained in a bird mosquito cycle, has been detected in more than 317 species of birds, particularly crows and jays.
Transmission
Primarily through the bite of an infected southern house mosquito (*Culex quinquefasciatus*). This mosquito breeds in standing water with heavy organic matter.

Incubation
3-15 days.

Reporting Classification
Class 1.

Epidemiology and Trends
In Mississippi, West Nile virus was first isolated in horses in 2001 followed by human infections in 2002 with 192 cases reported. The years following saw a decrease in the number of reported infections; however in 2006, there was a resurgence of 184 cases (Figure 1). In 2010, there were 8 reported cases with no deaths.

Figure 1

![West Nile Virus Rates by Year, United States and Mississippi, 2001-2010](chart)

*U.S. data: 66 cases in 2001.*

WNV is now thought to be endemic in Mississippi, and the mosquito vector is present the entire year. Human illness can occur year round, but is most prevalent from July to October. August and September are usually the peak months (Figure 2).
Of the 8 WNV cases reported in 2010, 5 (63%) were classified as WNV fever and 3 (38%) were encephalitis. The cases ranged in age from 7 to 77 years, with a median age of 51 years (Figure 3).

WNV infection can occur in any part of the state, and since 2001, activity (human cases, positive mosquito pools, horses or birds) has been reported in every Mississippi
County except Issaquena. The cases in 2010 were reported from the following counties: Calhoun (1), Coahoma (1), Leflore (3), Scott (1), Tallahatchie (1), and Tate (1).

A total of five mosquito pools tested positive for WNV in 2010. Horses may also become ill with WNV and can act as sentinels for the presence of infected mosquitoes. The Mississippi Board of Animal Health reports equine infections to MSDH. In 2010, two horses tested positive for WNV with one each being from Tippah and Forrest counties.

<table>
<thead>
<tr>
<th>Campylobacteriosis</th>

</tr>
<tr>
<td>2009 Case Total</td>
</tr>
<tr>
<td>2009 rate/100,000</td>
</tr>
</tbody>
</table>

**Clinical Features**

Campylobacteriosis is a zoonotic bacterial disease of variable severity ranging from asymptomatic infections to clinical illness presenting with diarrhea, abdominal pain, fever, and nausea and vomiting. Symptoms typically resolve after one week, but may persist for weeks if untreated. Rare post-infectious syndromes include reactive arthritis and Guillain-Barré syndrome (GBS).

**Infectious Agent**

*Campylobacter jejuni* (*C. jejuni*) causes most cases of diarrheal illness in humans.

**Reservoir**

Commonly present in cattle and poultry.

**Transmission**

Transmission mainly occurs through ingestion of undercooked meat, usually poultry, but occasionally contaminated food or water or raw milk. The number of organisms required to cause infection is low.

**Incubation**

Average incubation is 2-5 days, with a range from 1-10 days.

**Period of Communicability**

Person to person transmission does not typically occur, though the infected individual may shed organisms for up to 7 weeks without treatment.
Methods of Control
Disease prevention includes promotion of proper food handling, good hand washing, particularly after handling raw meats, and after contact with feces of dogs and cats. Pasteurizing milk and chlorinating water are also important. Symptomatic individuals should be excluded from food handling or care of patients in hospitals or long term care facilities.

Reporting Classification
Class 3.

Epidemiology and Trends
In 2010, there were 128 reported cases of campylobacteriosis in Mississippi; this was slightly increased from the 110 cases reported in 2009 and the three-year (2007-2009) average of 118 cases (Figure 4).

</table>

Campylobacter infections are typically more common in the warmer months, as are many enteric illnesses, with 41% of the total 2010 cases occurring in June, July, and August; however cases are reported to MSDH year round (Figure 5). The highest rates of infection are in children less than five years of age. In 2010, 28% of all reported cases were in children younger than five years of age (Figure 6).

**Clinical Features**

A sexually transmitted bacterial infection causing urethritis in males and cervicitis in females. Urethritis in men presents with scant to moderate mucopurulent urethral discharge, urethral itching, and dysuria. Cervicitis presents as a mucopurulent endocervical discharge, often with endocervical bleeding. The most significant complications in women are pelvic inflammatory disease and chronic infections, both of which increase the risk of ectopic pregnancy and infertility. Perinatal transmission of chlamydia occurs when an infant is exposed to the infected cervix during birth resulting in chlamydial pneumonia or conjunctivitis. Asymptomatic infection may be found in 1%-25% of sexually active men. Up to 70% of sexually active women with chlamydial infections may also be asymptomatic.

**Infectious Agent**

*Chlamydia trachomatis*, an obligate intracellular bacteria. Immunotypes D through K have been identified in 35-50% of nongonococcal urethritis.

**Reservoir**

Humans.

**Transmission**

Transmitted primarily through sexual contact.

**Incubation**

Incubation period is poorly defined, ranging from 7 to 14 days or longer.

**Period of Communicability**

Unknown.

**Methods of Control**

Prevention and control of chlamydia are based on behavior change, effective treatment, and mechanical barriers. Condoms and diaphragms provide some degree of protection from transmission or acquisition of chlamydia. Effective treatment of the infected patient and their partners, from 60 days prior to the onset of symptoms, is recommended.
**Reporting Classification**

Class 2.

**Epidemiology and Trends**

Chlamydia is the most frequently reported bacterial sexually transmitted disease in the United States and in Mississippi. In 2010, 21,422 cases of chlamydia were reported in Mississippi, a 13% increase from 2006 (19,001). Mississippi has reported case rates higher than the United States average (Figure 7) for several years, and when compared to other states, Mississippi has the country’s highest rate. The overall increase in cases can be partially attributed to aggressive statewide screening for chlamydia in all MSDH STD, family planning, and prenatal clinics beginning April 2004.

**Figure 7**

Chlamydia was reported in every public health district, with the highest incidence noted in Public Health District III (Figure 8).
Chlamydia infections were reported over a range of age groups, but the largest proportion was reported among 15-24 year olds, accounting for 76% of the reported cases (Figure 9). African Americans accounted for 83% of the reported cases in which race was known (Figure 10). In 2010, the rate of chlamydia infections for African Americans (1278.2 per 100,000) was nearly nine times the rate for whites (143.6 per 100,000).
Cryptosporidiosis

2010 Case Total 24  2010 rate/100,000 0.8
2009 Case Total 19  2009 rate/100,000 0.6

Clinical Features
A parasitic infection characterized by profuse, watery diarrhea associated with abdominal pain. Symptoms include anorexia, weight loss, fever, and nausea and vomiting less frequently. Symptoms often wax and wane and but generally disappear in 30 days or less in healthy people. Asymptomatic infections do occur. The disease may be prolonged and fulminant in immunodeficient individuals unable to clear the parasite. Children under 2, animal handlers, travelers, men who have sex with men, and close personal contacts of infected individuals are more prone to infection.

Infectious Agent
Cryptosporidium parvum, a coccidian protozoan, is associated with human infection.

Reservoir
Humans, cattle and other domesticated animals.

Transmission
Fecal-oral, which includes person-to-person, animal-to-person, waterborne (including recreational use of water) and foodborne transmission. Oocysts are highly resistant to
chemicals used to purify drinking water and recreational water (swimming pools, water parks). The infectious dose can be as low as 10 organisms.

**Incubation**
1 to 12 days (average 7 days).

**Period of Communicability**
As long as oocysts are present in the stool. Oocysts may be shed in the stool from the onset of symptoms to several weeks after symptoms resolve.

**Methods of Control**
Education of the public regarding appropriate personal hygiene, including handwashing. Symptomatic individuals with a diagnosis of cryptosporidiosis should not use public recreational water (e.g., swimming pools, lakes, ponds) while they have diarrhea and for at least 2 weeks after symptoms resolve. It is recommended that infected individuals be restricted from handling food, and symptomatic children be restricted from attending daycare until free of diarrhea. Prompt investigation of common food or waterborne outbreaks is important for disease control and prevention.

**Reporting Classification**
Class 3.

**Epidemiology and Trends**
There were 24 reported cases of cryptosporidiosis in 2010, which is comparable to 2009 with 19 reported cases. In a typical year, usually 3-29 cases are reported (Figure 11). The reported cases ranged in age from 3 months to 83 years (Figure 12).
**E. coli O157:H7/ HUS**

<table>
<thead>
<tr>

<td>24</td>
<td>0.8</td>
<td>0.2</td>
</tr>
<tr>
<td>2009</td>
<td>6</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

**Clinical Features**

*Escherichia coli* (E. coli) O157:H7 is the most virulent serotype of the Shiga toxin-producing *E. coli* (STEC), and is associated with diarrhea, hemorrhagic colitis, hemolytic-uremic syndrome (HUS), and postdiarrheal thrombotic thrombocytopenic purpura (ITP). Symptoms often begin as nonbloody diarrhea but can progress to diarrhea with occult or visible blood. Severe abdominal pain is typical, and fever is usually absent. The very young and the elderly are more likely to develop severe illness and HUS, defined as microangiopathic hemolytic anemia, thrombocytopenia, and acute renal dysfunction. HUS is a complication in about 8% of *E. coli* O157:H7 infections. Supportive care is recommended as antibiotic use may increase the risk of progression to HUS.

**Infectious Agent**

*E. coli* are gram negative bacilli. *E. coli* O157:H7 is thought to cause more than 90% of all diarrhea-associated HUS.

**Reservoir**

Cattle, to a lesser extent other animals, including sheep, deer, and other ruminants. Humans may also serve as a reservoir for person-to-person transmission.

**Transmission**

Mainly through ingestion of food contaminated with ruminant feces, usually inadequately cooked hamburgers; also contaminated produce or unpasteurized milk. Direct person-to-person transmission can occur in group settings. Waterborne transmission occurs both from contaminated drinking water and from recreational waters.

**Incubation**

2-10 days, with a median of 3-4 days.

**Period of Communicability**

Duration of excretion is typically 1 week or less in adults but can be up to 3 weeks in one-third of children. Prolonged carriage is uncommon.
Methods of Control

Education regarding proper food preparation and handling and good hand hygiene is essential in prevention and control. Pasteurization of milk and juice is important.

MSDH investigates all reported cases of HUS and E. coli O157:H7 infections. All isolates should be submitted to the Public Health Laboratory (PHL) for molecular subtyping, or DNA “fingerprinting”, with pulsed-field gel electrophoresis (PFGE). Isolate information is submitted to a national tracking system (PulseNet), a network of public health and food regulatory agencies coordinated by the CDC. This system facilitates early detection of common source outbreaks, even if the affected persons are geographically far apart, and assists in rapidly identifying the source of outbreaks.

Reporting Classification

Class 1.

Epidemiology and Trends

In 2010, twenty-four E. coli O157:H7 infections were reported to MSDH; seven of which resulted in HUS. On average, six infections have been reported annually over the past three years (2007-2009) (Figure 13). There were no deaths reported in Mississippi in 2010. Of the 43 cases of E. coli O157:H7/HUS that were reported to MSDH between 2007 and 2010, 58% occurred in children less than 10 years of age (Figure 14).

Thirteen (54%) of these infections were linked to a familial cluster in Oktibbeha County and ranged in age from 6 months to 57 years of age. Five of the cases required hospitalization and 3 developed HUS. Inadequate wastewater disposal was noted in propagating the spread of infection.

A separate cluster of three cases was associated with a daycare exposure in Washington County. All three of the cases required hospitalization and two developed HUS. No specific source of illness was identified.
* 2006 U.S. rate includes E. coli O157:H7; shiga toxin positive, serogroup non-O157; and shiga toxin positive, not serogrouped.
### Gonorrhea

<table>

<td>245.3</td>
</tr>
</tbody>
</table>

#### Clinical Features

A bacterial infection associated primarily with infection of the urogenital tract producing symptoms of discharge and dysuria. Other less common sites of infection include: pharynx, rectum, conjunctiva, and blood.

Complications associated with gonorrhea infection in men consist of epididymitis, penile lymphangitis, penile edema, and urethral strictures. The primary complication associated with gonorrhea infection in women is pelvic inflammatory disease, which produces symptoms of lower abdominal pain, cervical discharge, and cervical motion pain. Asymptomatic infections do occur. Pregnant women infected with gonorrhea may transmit the infection to their infants during a vaginal delivery. Infected infants can develop conjunctivitis leading to blindness if not rapidly and adequately treated. Septicemia can also occur in infected infants.

#### Infectious Agent

*Neisseria gonorrhoeae*, an intracellular gram-negative diplococcus.

#### Reservoir

Humans.

#### Transmission

Gonorrhea is transmitted primarily by sexual contact, but transmission from the infected cervix to an infant during birth occurs.

#### Incubation

In men, the incubation period is primarily 2-5 days, but may be 10 days or longer. In women, it is more unpredictable, but most develop symptoms less than 10 days after exposure.

#### Period of Communicability

In untreated individuals, communicability can last for months; but if an effective treatment is provided communicability ends within hours.
**Methods of Control**

Prevention and control of gonorrhea are based on education, effective treatment, and mechanical barriers. Condoms and diaphragms provide some degree of protection from transmission or acquisition of gonorrhea. Effective treatment of the infected patient and their partners from 60 days prior to the onset of symptoms is recommended.

**Reporting Classification**

Class 2.

**Epidemiology and Trends**

Gonorrhea is the second most commonly reported notifiable disease in the United States. In Mississippi, from 2003-2007, the number of gonorrhea cases increased 31.4%, from 6,328 to 8,315 cases (Figure 15). Although there was a slight decrease in cases since 2007, Mississippi still has the highest case rate of gonorrhea in the United States.

**Figure 15**

Gonorrhea was reported in every public health district, with the highest incidence noted in Public Health District III (Figure 16).
Although the burden of disease impacted individuals in most of the age groups, 70% of reported cases were among 15-24 year olds (Figure 17). African Americans accounted for 90% of the reported cases in which race was known (Figure 18). In 2010, the rate of gonorrhea infections for African Americans (420.7 per 100,000) was sixteen times the rate of whites (26.1 per 100,000).
Clinical Features

Haemophilus influenzae, type b (Hib) is an invasive bacterial disease, particularly among infants, that can affect many organ systems. Invasive disease usually begins as a bloodstream infection, with bacteria spreading to distant sites. Epiglottitis, pneumonia, septic arthritis, and septicemia are other forms of invasive disease. Hib meningitis presents with fever, decreased mental status and nuchal rigidity. Neurologic sequelae can occur in 15-30% of survivors, with hearing impairment the most common. Case fatality rate is 2-5% even with antimicrobial therapy. Peak incidence is usually in infants 6-12 months of age; Hib disease rarely occurs beyond 5 years of age. In the prevaccine era, meningitis accounted for 50-60% of all cases of invasive disease. Since the late 1980’s, with the licensure of Hib conjugate vaccines, Hib meningitis has essentially disappeared in the U.S.

Infectious Agent

Haemophilus influenzae type b, a gram-negative encapsulated bacterium.

Reservoir

Humans, asymptomatic carriers.
**Transmission**
Respiratory droplets and contact with nasopharyngeal secretions during the infectious period.

**Incubation**
Uncertain; probably short, 2-4 days.

**Period of Communicability**
As long as organisms are present and up to 24-48 hours after starting antimicrobial therapy.

**Methods of Control**
Two Hib conjugate vaccines are licensed for routine childhood vaccination. The number of doses in the primary series is dependent on the type of vaccine used. A primary series of PRP-OMP (PedvaxHIB®) vaccine is two total doses, at 2 and 4 months of age; the primary series with PRP-T (ActHIB®) requires three total doses, given at 2, 4 and 6 months of age. A booster dose at 12-15 months of age is recommended regardless of which vaccine is used for the primary series. Vaccination with Hib containing vaccines may decrease the carriage rate, decreasing the chances of infection in unvaccinated in children. Immunization is not recommended for children over 5 years of age.

The Mississippi State Department of Health (MSDH) investigates all reported suspected Hib cases and provides prophylactic antibiotics (rifampin) for all household contacts with one or more children under one year old or in households with children 1-3 years old who are inadequately immunized. During investigation, contacts are often treated before the isolate’s serotype is known. MSDH requests that all *Haemophilus influenzae* isolates be sent to the Public Health Laboratory (PHL) for serotyping.

**Reporting Classification**
Class 1.

**Epidemiology and Trends**
Prior to the development and widespread use of Hib conjugate vaccines in the late 1980’s and early 1990’s, Hib was the most common cause of bacterial meningitis in children < 5 years of age. In Mississippi, conjugate vaccine was first offered to 18 month olds in 1989, to 15 month olds in 1990, and as a primary series, starting at 2 months of age, with a 12-15 month booster, in January 1991. With the institution of vaccination, the number of reported cases of invasive disease dropped from 82 in 1989, to 5 by 1994. There have been less than 5 cases per year since 1995.
In 2010, there were 15 cases of invasive disease due to *Haemophilus influenzae* reported to MSDH. None of these reported cases of *H. influenzae* were determined to be type b.

### Hepatitis A

<table>
<thead>
<tr>
<th></th>
<th>2010 Case Total</th>

</tr>
</thead>
<tbody>
<tr>
<td>2010 Case Total</td>
<td>2</td>
<td>0.1</td>
</tr>
<tr>
<td>2009 Case Total</td>
<td>9</td>
<td>0.3</td>
</tr>
</tbody>
</table>

### Clinical Features
Hepatitis A is a viral illness with an abrupt onset of fever, malaise, anorexia, nausea, vomiting, and abdominal pain, followed by jaundice in a few days. The disease varies in intensity from a mild illness of 1-2 weeks, to a severe disease lasting several months. Most cases among children are asymptomatic and the severity of illness increases with age; the case fatality rate is low—0.1%-0.3%. No chronic infection occurs.

### Infectious Agent
Hepatitis A virus (HAV), an RNA virus.

### Reservoir
Humans, rarely chimpanzees and other primates.

### Transmission
Transmission occurs through the fecal-oral route either by person to person contact or ingestion of contaminated food or water. Common source outbreaks may be related to infected food handlers. Many younger children are asymptomatic, but shed virus and are often sources of additional cases.

### Incubation
Average 28-30 days, (range 15-50 days).

### Period of Communicability
Infected persons are most likely to transmit HAV 1-2 weeks before the onset of symptoms and in the first few days after the onset of jaundice, when viral shedding in the stool is at its highest. The risk of transmission then decreases and becomes minimal after the first week of jaundice.

### Methods of Control
In the prevaccine era, hygienic measures and post-exposure immune globulin were the primary means of preventing infection. Vaccine was first introduced in 1995, and
following successful vaccination programs in high incidence areas, the Advisory Committee on Immunization Practices (ACIP) recommended routine vaccination for all children in 2005. Children aged 12-23 months of age should receive one dose of hepatitis A vaccine followed by a booster 6-18 months later, with catch up vaccination for children not vaccinated by 2 years of age.

Post-exposure prophylaxis is recommended, within two weeks of exposure, for all susceptible individuals who are close personal contacts of, or attend daycare with infected individuals, or are exposed to hepatitis A virus through common source outbreaks. Hepatitis A vaccine (with completion of the series) is recommended for post-exposure prophylaxis for all healthy persons aged 12 months to 40 years. Immune globulin should be considered for children less than 12 months of age, adults over 40 years of age, and those in whom vaccination is contraindicated. Use of both simultaneously can be considered with higher risk exposures. Post-exposure prophylaxis is not generally indicated for healthcare workers unless epidemiological investigation indicates ongoing hepatitis A transmission in the facility.

**Reporting Classification**

Class 1.

**Epidemiology and Trends**

There were two hepatitis A cases reported in Mississippi in 2010. This was significantly less than the nine cases reported in 2009 and the three year (2007-2009) average of eight annual cases (Figure 19). Both cases were in adults over the age of 18 and neither was related to a common source outbreak.
**Hepatitis B, acute**

2010 Case Total 34  
2009 Case Total 32

**Clinical Features**

An acute viral illness characterized by the insidious onset of anorexia, abdominal discomfort, nausea and vomiting. Clinical illness is often unrecognized because jaundice occurs in only 30-50% of adults and fewer than 10% of children. Approximately 5% of all acute cases progress to chronic infection. Younger age at infection is a risk factor for becoming a chronic carrier with 90% of perinatally infected infants becoming chronic carriers. Chronic cases may have no evidence of liver disease, or may develop clinical illness ranging from chronic hepatitis, to cirrhosis, liver failure or liver cancer. Hepatitis B infections are the cause of up to 80% of hepatocellular carcinomas worldwide.

**Infectious Agent**

Hepatitis B virus, a hepadnavirus.

**Reservoir**

Humans.
Transmission
Transmission occurs through parenteral or mucosal exposure to body fluids of hepatitis B surface antigen (HBsAg) positive persons, such as perinatal exposure, through contact with contaminated needles, or through sexual contact. Blood and blood products, saliva, semen and vaginal secretions are known to be infectious. The three main groups at risk for hepatitis B infection are heterosexuals with infected or multiple partners, injection-drug users, and men who have sex with men.

Incubation
45-180 days, average 60-90 days.

Period of Communicability
As long as HBsAg is present in blood. In acute infections, surface Ag can be present 1-2 months after onset of symptoms.

Methods of Control
Routine hepatitis B vaccination series is recommended for all children beginning at birth, with catch-up at 11-12 years of age if not previously vaccinated. The usual three dose schedule is 0, 1-2, and 6-18 months. Vaccination is also recommended for high risk groups, including those with occupational exposure, household and sexual contacts of HBsAg positive individuals (both acute and chronic infections), and injecting drug users.

Transmission of hepatitis B can be interrupted by identification of susceptible contacts and HBsAg positive pregnancies, and the timely use of post-exposure prophylaxis with vaccine and/or immune globulin.

Perinatal transmission is very efficient in the absence of post-exposure prophylaxis, with an infection rate of 70-90% if the mother is both HBsAg and hepatitis B e antigen (HBeAg) positive. The risk of perinatal transmission is about 10% if the mother is only HBsAg positive. MSDH, through the Perinatal Hepatitis B Program, tracks HBsAg positive pregnant women, provides prenatal HBsAg testing information to the delivery hospitals when available, and monitors infants born to infected mothers to confirm completion of the vaccine series by 6 months of age, and then tests for post-vaccine response and for possible seroconversion at 9-12 months of age. Post-exposure prophylaxis is highly effective in preventing hepatitis B vertical transmission, therefore, testing of all pregnant women for HBsAg is recommended with each pregnancy.

Reporting Classification
Class 2.
Epidemiology and Trends

In 2010, 34 cases of acute hepatitis B were reported. This was comparable to the 32 cases reported in 2009, but lower than the three year average (2007-2009) of 44 cases reported annually (Figure 20). Twenty-two (65%) of the 34 reported cases occurred in individuals aged 15-34 years. There were five cases (15%) reported in individuals aged 40-45 years. Overall, the cases ranged in age from 15 to 44 years (Figure 21).

</table>
A comprehensive strategy to eliminate hepatitis B virus transmission was recommended in 1991; it includes prenatal testing of pregnant women for HBsAg to identify newborns that require immunoprophylaxis for prevention of perinatal infection and to identify household contacts who should be vaccinated, routine vaccination of infants, vaccination of adolescents, and vaccination of adults at high risk for infection.

In 2010, 46 HBsAg positive pregnant women were reported to the Perinatal Hepatitis B Prevention Program (Figure 22). This was lower than the 82 reported in 2009 and the three year average of 95. There were no reported cases of HBsAg positive infants born to HBsAg positive mothers in 2010. This was similar to 2009 and 2008; however in 2007, there were two cases of perinatal transmission.

**Figure 22**

<td></td>
</tr>
</tbody>
</table>

**Clinical Features**

The clinical spectrum of human immunodeficiency virus (HIV) infection varies from asymptomatic infections to advanced immunodeficiency with opportunistic complications. One half to two thirds of recently infected individuals have manifestations of an infectious mononucleosis-like syndrome in the acute stage. Fever, sweats, malaise, myalgia, anorexia, nausea, diarrhea, and non-exudative pharyngitis
are prominent symptoms in this stage. Constitutional symptoms of fatigue and wasting may occur in the early months or years before opportunistic disease is diagnosed. Over time, HIV can weaken the immune system, lowering the total CD4 count and leading to opportunistic infections and the diagnosis of Acquired Immunodeficiency syndrome (AIDS).

**Infectious Agent**

Human immunodeficiency virus is a retrovirus with two known types, HIV-1 and HIV-2. These two types are serologically distinct and have a different geographical distribution, with HIV-1 being primarily responsible for the global pandemic and the more pathogenic of the two.

**Reservoir**

Humans.

**Transmission**

HIV infection can be transmitted from person to person during sexual contact, by blood product transfusion, sharing contaminated needles or infected tissue or organ transplant. Transmission by contact with body secretions like urine, saliva, tears or bronchial secretions has not been recorded. Without appropriate prenatal treatment, 15-30% of infants born to HIV positive mothers are infected. Breast feeding is also a known cause of mother to infant transmission of HIV.

**Incubation**

The period from the time of infection to the development of AIDS ranges from 1 year up to 15 years or longer. The availability of effective anti-HIV therapy has greatly decreased the development of AIDS among HIV infected individuals in the U.S.

**Period of Communicability**

Individuals become infectious shortly after infection and remain infectious throughout the course of their lives.

**Methods of Control**

Abstinence is the only sure way to avoid sexual HIV transmission; otherwise mutual monogamy with partners known to be uninfected and/or the use of latex condoms are known to reduce the risk of infection. Confidential HIV testing and counseling and testing of contacts, prenatal prevention by counseling and testing all pregnant women, and treatment with appropriate anti-retroviral therapy can reduce transmission. Post-exposure prophylaxis for health care workers exposed to blood or body fluids suspected to contain HIV is an important worksite preventive measure. MSDH performs contact investigation, counseling and testing for each reported case of HIV infection.
**Reporting Classification**

Class 1.

**Epidemiology and Trends**

Both HIV infection and AIDS are reportable at the time of diagnosis, so many patients will be reported twice (once at first diagnosis of HIV infection, and again when developing an AIDS defining illness). The epidemiologic data that follows is regarding the initial report of HIV disease, whether first diagnosed as HIV infection or AIDS. Over the past few years, there has been little change in HIV disease trends. There were 550 cases of HIV disease reported in 2010, an 8% decrease from 2006 (599) (Figure 23).

**Figure 23**

| HIV Disease Rates by Year, Mississippi, 2006-2010 |
|-----------------|-----------------|-----------------|-----------------|-----------------|-----------------|
| Incidence per 100,000 population |
| 0.0 | 5.0 | 10.0 | 15.0 | 20.0 | 25.0 | 30.0 | 35.0 |
| 2006 | 2007 | 2008 | 2009 | 2010 |
| HIV Disease Rate (MS) | 20.6 | 20.9 | 20.6 | 20.7 | 18.5 |
| HIV Disease Cases (MS) | 599 | 611 | 606 | 610 | 550 |

Individuals from every Public Health District were impacted by this disease. Public Health District V reported the highest case rate, statewide, followed by District III (Figure 24).
HIV disease was reported in all age groups, with 55% of the cases reported among 20-39 year olds (Figure 25). African Americans were disproportionately impacted by HIV disease. In 2010, 79% of new cases were among African Americans in which race was known (Figure 26).
Influenza

Clinical Features
An acute viral infection of the respiratory tract characterized by sudden onset of fever, often with chills, headache, malaise, diffuse myalgia, and nonproductive cough. The highest risks for complications from seasonal influenza are in persons aged 65 years and older, young children, pregnant and postpartum women, and persons at any age with chronic underlying illnesses. Pneumonia due to secondary bacterial infections is the most common complication of influenza. During the period 1976—2007, estimated influenza deaths ranged from a low of 3,349 to a high of 48,614 per year in the United States.

Additional References:

- CDC. Guidelines for national immunodeficiency virus case surveillance, including monitoring for human immunodeficiency virus infection and acquired immunodeficiency syndrome. MMWR 1999/48(RR13;1-28.

**Infectious Agent**
Influenza is caused by an RNA virus. There is usually one predominant subtype of influenza virus causing the majority of infection each influenza season; however both influenza A (H1N1 and H3N2) and influenza B have circulated each season.

**Reservoir**
Humans

**Transmission**
Transmission occurs person to person by direct or indirect contact with virus laden droplets or respiratory secretions.

**Incubation**
The incubation period usually is 1 to 4 days, with a mean of 2 days.

**Period of Communicability**
From 1 day before clinical onset through 3-5 days from clinical onset in adults; and up to 7-10 days from clinical onset in young children.

**Methods of Control**
Yearly vaccination is recommended with either trivalent inactivated vaccine (TIV) or live attenuated influenza vaccine (LAIV). Education on basic personal hygiene, specifically transmission from unprotected coughs and sneezes and from hand to mucous membrane is highly important in preventing or slowing transmission of influenza. Antivirals can also be used to prevent and treat influenza. The neuraminidase inhibitors (oseltamivir and zanamivir), continue to be effective against all forms of influenza. Fortunately, influenza A (H1N1) and A (H3N2), as well as influenza B viruses continue to be sensitive to the neuraminidase inhibitors. High levels of resistance to the adamantanes (amantadine and rimantadine) persist among influenza A (H1N1) and A (H3N2) viruses circulating globally. The adamantanans are not effective against influenza B viruses. Please consult the Centers for Disease Control and Prevention (CDC), Prevention and Control of Influenza with Vaccines: Recommendations of the Advisory Committee on Immunization Practices (ACIP), 2010. MMWR 59(No. RR-8); August 6, 2010. [http://www.cdc.gov/mmwr/pdf/rr/rr5908.pdf](http://www.cdc.gov/mmwr/pdf/rr/rr5908.pdf) and the brief update Prevention and Control of Influenza with Vaccines: Recommendations of the Advisory Committee on Immunization Practices (ACIP), 2011. MMWR 60(33); 1128-1132; August 26, 2011. [http://www.cdc.gov/mmwr/PDF/wk/mm6033.pdf](http://www.cdc.gov/mmwr/PDF/wk/mm6033.pdf)

**Reporting Classification**
Class 1: Influenza-associated pediatric deaths (<18 years of age).
Epidemiology and Trends

Influenza activity usually occurs from December through March or April, but can occur earlier or later. Peak activity typically occurs in February or March. The risk of complications depends on many factors, including age and underlying medical conditions. Vaccination status and the match of vaccine to circulating viruses affect both the susceptibility to infection and the possibility of complications. Outbreaks can occur in group settings, such as nursing homes.

MSDH monitors seasonal influenza activity statewide through an active syndromic surveillance program reported by sentinel providers. In the 2010-2011 influenza season, 35 sentinel providers in 30 counties were enrolled in this system, representing hospital emergency departments, urgent care and primary care clinics, and college and university student health centers. These providers reported weekly numbers of nontrauma patient visits consistent with an influenza-like illness (ILI), defined as fever >100°F and cough and/or sore throat in the absence of a known cause other than influenza. MSDH uses this information to estimate the magnitude of the state’s weekly influenza activity. These data are also used to estimate the geographic spread of influenza within the state, ranging from no activity to widespread activity. This terminology represents a geographic estimate rather than an indication of severity of the season. ILI providers are also supplied with kits for PCR influenza testing at the Public Health Laboratory (PHL).

The 2009-2010 influenza season was dominated by the pandemic strain of influenza A (2009 H1N1). After the peak of activity during the late summer and fall of 2009, influenza activity remained at a lower but still significant level until April 2010.

The 2010-2011 influenza season was mild. It began with increasing reports of influenza-like illness reaching a peak in December (Figure 27). This portion of the 2010-2011 season was dominated by Influenza B. As the season progressed into calendar year 2011, the dominant virus shifted to Influenza A (H3N2), although some cases of Influenza A (2009 H1N1) and Influenza B continued to occur (Figure 28).
**Legionellosis**

<table>

</thead>
<tbody>
<tr>
<td></td>
<td>12</td>
<td>0.4</td>
<td>4</td>
<td>0.1</td>
</tr>
</tbody>
</table>

**Clinical Features**
Legionellosis is an acute bacterial infection that has two clinical syndromes; Legionnaires’ disease and Pontiac fever. Both syndromes can present with fever, headache, diarrhea and generalized myalgias. Those with Legionnaires’ disease develop a non-productive cough and pneumonia that can be severe and progress to respiratory failure. Even with improved diagnosis and treatment, case fatalities rates are approximately 15%. Pontiac fever is a self-limited illness that does not progress to pneumonia or death.

**Infectious Agent**
Legionella pneumophila (L. pneumophila), a gram negative bacillus with 18 serogroups. L. pneumophila serogroup 1 is the most common serogroup associated with illness.

**Reservoir**
Legionellosis is a waterborne disease. The best conditions for growth of the bacteria are warm water temperatures, stagnation, sediment and low levels of biocide.

**Transmission**
Airborne transmission occurs when water sources contaminated with L. pneumophila are aerosolized. Common sources of outbreaks are potable water systems, whirlpools/spas and cooling towers.

**Incubation**
Legionnaires’ disease — 2-10 days, most commonly 5-6 days. Pontiac Fever — 5-72 hours, most commonly 24-48 hours.

**Period of Communicability**
Legionellosis is not transmitted person to person.

**Reporting Classification**
Class 2.

**Epidemiology and Trends**
In 2010, there were 12 reported cases of Legionnaire’s disease in Mississippi. There were no deaths of Mississippi residents reported. On average, 2 infections have been
reported annually over the past 3 years (Figure 29). Cases ranged in age from 20 to 78 years. Five of these cases were outbreak associated, please refer to the “Events of Public Health Significance” section on page 91.

**Clinical Features**

A bacterial illness that in immunocompetent adults may present as an acute, mild febrile illness. In the elderly, immunocompromised persons, diabetics, alcoholics and in newborns, illness may present as meningoencephalitis and/or septicemia. The onset of meningoencephalitis can be sudden with fever, intense headache, nausea, vomiting and signs of meningeal irritation. Infected pregnant women may be asymptomatic or experience only a mild febrile illness; however, infection during pregnancy can lead to miscarriage or stillbirth, premature delivery, or infection of the newborn. The case fatality rate is as high as 30-50% in newborns.

**Infectious Agent**

*Listeria monocytogenes*, a gram-positive, rod-shaped bacterium.
**Reservoir**
Mainly occurs in soil, forage, water, mud and silage. Animal reservoirs include domestic and wild mammals, fowl and people. Asymptomatic fecal carriage is as high as 10% in humans.

**Transmission**
Ingestion of unpasteurized or contaminated milk and soft cheeses, as well as vegetables and ready-to-eat meats, such as deli meats or hot dogs. Unlike most other foodborne pathogens, *Listeria* tends to multiply in contaminated foods that are refrigerated. In neonates, infection can be transmitted in utero or by passage through the infected birth canal.

**Incubation**
Variable, estimated median incubation is 3 weeks (range 3-70 days)

**Period of Communicability**
Mothers of infected newborns can shed the bacterium in vaginal discharges and urine for 7-10 days post delivery. Infected individuals can shed the bacteria in their stools for several months.

**Methods of Control**
Education for proper food handling and preparation. Avoid unpasteurized (raw) milk or foods made from unpasteurized milk, such as soft cheeses, which can support the growth of organisms during ripening. Consume perishable and ready-to-eat foods as soon as possible after purchase, and cook hot dogs thoroughly before consumption. These recommendations are especially important during pregnancy. MSDH investigates all reported cases for rapid identification of common source outbreaks.

**Reporting Classification**
Class 2.

**Epidemiology and Trends**
There were five reported cases of listeriosis in Mississippi in 2010, which was comparable to 2009 and with the average number of cases reported for the past three years. The incidence rate in Mississippi has remained below national rates since *Listeria* was added to the National Notifiable Disease List in 2000 (Figure 30).
There were no neonatal infections reported in 2010. The five reported cases ranged in age from 3 to 89 years old. One death was reported in a 76 year old. None of the infections were epidemiologically linked or associated with common source outbreaks.

**Lyme Disease**

<table>

<td>0.0</td>
</tr>
</tbody>
</table>

**Clinical Features**

A tick-borne bacterial disease characterized primarily by a distinct “bull’s-eye” rash (erythema migrans) in the early stage of the infection. The rash is present in up to 60%-80% of patients. Accompanying symptoms may include malaise, fever, headache, stiff neck, myalgias, migratory arthralgias and/or lymphadenopathy. In untreated patients, chronic or late manifestations may include musculoskeletal symptoms (joint swelling or chronic arthritis), neurological manifestations (aseptic meningitis, cranial neuritis, facial palsy, rarely encephalomyelitis), and cardiac abnormalities (specifically 2nd or 3rd degree atrioventricular conduction defects).

**Infectious Agent**

*Borrelia burgdorferi*, a spirochete.
**Reservoir**
Small mammals, mainly mice. Deer are efficient maintenance hosts and play an important role in transporting ticks.

**Transmission**
Transmission occurs through the bite of an infected *Ixodes scapularis* tick (black-legged tick). Nymphs are more likely to transmit disease, and they feed primarily on small mammals. Studies indicate the tick usually must be attached 24 hours or longer to efficiently transmit the bacteria. No person to person transmission or maternal fetal transmission has been confirmed.

**Incubation**
2-30 days after tick exposure for erythema migrans, however, early infection may be unapparent and patients may present weeks to months after exposure with late manifestations.

**Methods of Control**
Avoid tick infested areas when possible. When unavoidable, use tick repellant and measures to decrease tick exposure. After leaving tick prone areas examine body well and remove any ticks. It is important to promptly remove any attached ticks; it is not necessary to remove the head.

**Reporting Classification**
Class 2.

**Epidemiology and Trends**
Most cases occur in late spring and summer. Lyme disease is not considered endemic in Mississippi, although the vector is present in the state. Since 2004 the number of annual reported cases has ranged from 0-3. There were no confirmed cases reported in 2010, but there were two cases in 2007.

**Measles**

<table>
<thead>
<tr>
<th>Year</th>
<th>Case Total</th>
<th>2010 rate/100,000</th>
<th>2009 rate/100,000</th>
</tr>
</thead>

<td>0.0</td>
<td>0.0</td>
</tr>
<tr>
<td>2009</td>
<td>0</td>
<td>0.0</td>
<td>0.0</td>
</tr>
</tbody>
</table>

**Clinical Features**
Measles is a highly contagious viral illness characterized by cough, coryza, conjunctivitis (3 C’s), fever, an erythematous maculopapular rash, and a pathognomonic enanthema (Koplik spots). Complications are seen more frequently in children younger
than 5 years of age and in adults 20 years of age and older. Diarrhea, pneumonia and encephalitis are the most common complications seen. The risk of death is higher in these age groups as well; the most common cause of death is pneumonia in children, and acute encephalitis in adults. Subacute sclerosing panencephalitis is a rare degenerative central nervous system disease that is thought to be due to persistent measles infection of the brain, and typically presents approximately 7 years after initial infection.

**Infectious Agent**
Measles virus, in the paramyxovirus family.

**Reservoir**
Humans.

**Transmission**
Transmitted by direct contact with large infectious droplets or, less commonly, by airborne spread. Measles is highly contagious, and all persons without previous disease or vaccination are susceptible.

**Incubation**
Eight to ten days.

**Period of Communicability**
Three to five days before to four days after rash onset.

**Methods of Control**
Measles, mumps and rubella (MMR) vaccine is recommended for all children at 12 to 15 months of age with a second dose at school entry (4 to 6 years of age). Appropriate two dose vaccination induces immunity in 99% of individuals.

MSDH investigates all reported cases and provides prophylaxis for all contacts as appropriate. Measles vaccine administered within 72 hours of exposure may provide protection in some cases. Immunoglobulin, given within six days of exposure, can prevent or modify measles in susceptible persons who are at high risk for complications.

During 2001–2010, a total of 159 imported cases were reported in U.S. residents, including 47 in children aged 6–23 months. Because measles remains endemic in much of the world, international travelers should be up-to-date on vaccinations. In accordance with the Advisory Committee for Immunization Practices (ACIP) recommendations, U.S. children who travel or live abroad should be vaccinated at an
earlier age than those living in the United States because of the greater risk for exposure to measles outside the United States, and particularly outside the Americas.

**Reporting Classification**

Class 1.

**Epidemiology and Trends**

Measles occurs throughout the world with peak incidence usually in late winter and spring. There have been no reported cases of measles in Mississippi since 1992, when there were 17 reported cases. Fifteen of those cases were associated with an outbreak at the University of Mississippi and the index case’s infection in that outbreak was traced to an exposure in Europe. Following this outbreak, a history of 2 doses of MMR was required to attend public universities in Mississippi.

Widespread measles immunization has led to the interruption of endemic transmission of measles in the United States and Mississippi. However, measles continues to be endemic or has become endemic again in several countries, particularly in Europe, due in part to dropping immunization rates. Sporadic outbreaks are reported in the U.S. and are largely due to imported cases. Transmission from these cases easily occurs in communities with high numbers of unvaccinated persons. Continued high vaccine rates in the U.S. and in Mississippi are important to provide appropriate population immunity and decrease the risk to those who are too young to receive vaccine or have medical contraindications to vaccination.

### Meningococcal disease, invasive

<table>
<thead>
<tr>
<th>Year</th>
<th>Case Total</th>
<th>Rate/100,000</th>
</tr>
</thead>
<tbody>
<tr>
<td>2010</td>
<td>5</td>
<td>0.2</td>
</tr>
<tr>
<td>2009</td>
<td>5</td>
<td>0.2</td>
</tr>
</tbody>
</table>

**Clinical Features**

Invasive meningococcal disease is an acute bacterial illness characterized by meningitis and/or meningococcemia that may rapidly progress to purpura fulminans, shock and death. Symptoms include rapid onset of fever, severe headache, stiff neck, nausea and vomiting, and possibly a petechial rash. The case fatality rate, even with the use of antibiotics and improved supportive measures, remains high at 8-15%. Long term sequelae occur in 10-20% of survivors and include hearing loss and mental retardation.
Infectious Agent

*Neisseria meningitidis* (*N. meningitidis*), a gram negative aerobic diplococcus. The most common serogroups in the United States are B, C, W-135, and Y. Licensed vaccines are not protective against serogroup B.

Reservoir

Humans. Up to 5-10% of the population may be asymptomatic carriers.

Transmission

Transmission of *N. meningitidis* is person to person by direct contact with respiratory droplets from the nose and throat of infected individuals or carriers. Less than 1% of colonized individuals will progress to invasive disease.

Incubation

The incubation period is 2-10 days, commonly 3-4 days.

Period of Communicability

Individuals remain contagious until meningococci are no longer present in nasal or throat secretions, usually 24 hours after antibiotic treatment has begun.

Methods of Control

Vaccination and post-exposure prophylaxis are effective in preventing invasive meningococcal disease. Routine vaccination with the quadrivalent meningococcal conjugate vaccine (MCV4) is recommended for all children aged 11-12 years, children aged 13-18 years not previously vaccinated, and any person aged 2-55 years with increased risk for meningococcal disease (terminal complement deficiencies, functional or anatomic asplenia, college freshman living in dormitories, and travelers to countries in which *N. meningitidis* is hyperendemic or epidemic). Use of the meningococcal polysaccharide vaccine (MPSV) should be limited to persons older than 55 years of age, or used when MCV4 is not available.

MSDH investigates each reported case and provides prophylactic antibiotics (rifampin) for household contacts and other appropriate close contacts. Health care workers are not usually at risk unless there is direct contact with nasopharyngeal secretions (mouth-to-mouth resuscitation).

Reporting Classification

Class 1.
Epidemiology and Trends

In 2010, there were five reported cases of invasive meningococcal disease. This is comparable to the number of reported cases in 2009. Typically, over the last decade, 5-24 cases are reported annually in Mississippi (Figure 31). Nationally, infants less than 12 months of age have the highest incidence of invasive disease. In the U.S., rates of disease decline in early childhood, increase during adolescence and early adulthood, then decrease again in older adults. The 2010 MS cases ranged in age from 20 days to 92 years, with 60% of the cases being less than five years of age (Figure 32).

MSDH requests that all isolates be submitted to the PHL for typing. Two of the confirmed cases in 2010 were typed as serogroup B. The serogroups for the other 3 cases were unknown or not able to be subtyped.

In total, rifampin prophylaxis was provided for 23 contacts of a meningococcal disease case in 2010; eight (35%) of which were less than 18 years of age. There were no confirmed deaths reported in 2010 from meningococcal disease.

Figure 31
Clinical Features
A viral illness with acute onset of fever, tenderness and swelling in one or more of the salivary glands. Parotitis is the most common presentation, but asymptomatic infections do occur. Symptoms typically resolve within 7-10 days. Orchitis in postpubertal males and oophoritis in postpubertal females are the most frequent complications.

Infectious Agent
Mumps virus, in the paramyxovirus family.

Reservoir
Humans.

Transmission
Spread through airborne transmission or by direct contact with infected droplet nuclei or saliva.

Incubation
About 16 – 18 days (range 14 – 25).
**Period of Communicability**

Three days before to four days after onset of symptomatic disease. Virus has been isolated from saliva up to 7 days before and 9 days after onset of parotitis.

**Methods of Control**

Measles, mumps and rubella (MMR) vaccine routinely given at 12 – 15 months of age with a second dose at 4 – 6 years. Immunization of susceptible contacts may be helpful in prevention of infection.

**Reporting Classification**

Class 2.

**Epidemiology and Trends**

In Mississippi, there are typically 1-2 cases reported annually. In 2010, there were no reported mumps cases, compared to one case in 2009.

### Pertussis

<table>
<thead>
<tr>
<th>Year</th>
<th>Case Total</th>
<th>2010 rate/100,000</th>
<th>2009 rate/100,000</th>
</tr>
</thead>
<tbody>
<tr>
<td>2010</td>
<td>106</td>
<td>3.6</td>
<td></td>
</tr>
<tr>
<td>2009</td>
<td>80</td>
<td>2.7</td>
<td></td>
</tr>
</tbody>
</table>

**Clinical Features**

An acute bacterial disease of the respiratory tract distinguished by prolonged paroxysmal coughing with a characteristic inspiratory “whoop.” There are three clinical stages: catarrhal stage, paroxysmal cough stage, and a convalescent stage. Post-tussive vomiting is common in the paroxysmal stage. Infants under 6 months of age, vaccinated children, adolescents and adults often do not have whoop or paroxysms. Pneumonia is the most frequent complication; the majority of fatalities occur in children under 6 months of age. Adults and adolescents may have a mild illness which often is undiagnosed, but serve as a source of infection for unvaccinated or incompletely vaccinated children.

**Infectious Agent**

*Bordatella pertussis*, an aerobic gram negative rod.

**Reservoir**

Humans. Adolescents and adults are reservoirs for *B. pertussis* and are often the source of infection in infants.
**Transmission**
Direct contact with respiratory secretions by airborne route, probably via droplets.

**Incubation**
Average 9-10 days. (Range 6-20 days).

**Period of Communicability**
Most transmissible in the catarrhal stage (which lasts about 1 week) and then during the first 2 weeks after onset of paroxysmal cough, or a total of 21 days after symptom onset. Communicability then gradually decreases and becomes negligible. Individuals are no longer considered contagious after 5 days of antibiotic treatment.

**Methods of Control**
Vaccination and post-exposure prophylaxis are effective in preventing pertussis. Pertussis vaccine is combined with diphtheria and tetanus toxoids (DTaP); the primary series consists of four doses given between the ages of 2 months and 18 months, with a booster at 4-6 years of age.

Pertussis immunity wanes 5-10 years after the booster vaccine, leaving adolescents and adults more vulnerable to infection. A pertussis containing vaccine (Tdap) was recently approved for the vaccination of adolescents and adults. Adolescents and adults should receive a single dose of Tdap to replace a single dose of tetanus (Td).

MSDH investigates each reported case and provides prophylactic antibiotics (erythromycin, azithromycin) for all household contacts where there is a child less than one year of age or a pregnant woman in the last three weeks of her pregnancy in the home.

**Reporting Classification**
Class 1.

**Epidemiology and Trends**
Among the diseases for which universal childhood vaccination is recommended, pertussis is consistently the one that has the highest number of cases annually. Susceptibility of unimmunized persons is universal.

In 2010, there were 106 reported cases of pertussis infections, but many more go undiagnosed and unreported. This is higher than the 80 cases which were reported in 2009, but comparable to the 104 cases reported in 2008. The three year average for 2007-2009 was 147 cases (Figure 33).
Infants less than 1 year of age, who are at greatest risk for severe disease and death, continue to have the highest reported rate of pertussis. Forty-one (39%) of the cases in 2010 were among children less than 1 year of age (Figure 34). No pertussis deaths were reported in 2010.
Pneumococcal disease, invasive

<table>
<thead>
<tr>
<th>Pneumococcal disease, invasive, children less than 5 years of age</th>
</tr>
</thead>
<tbody>
<tr>
<td>2010 Case Total</td>
</tr>
<tr>
<td>2009 Case Total</td>
</tr>
</tbody>
</table>

Clinical Features
An acute bacterial infection with two clinical invasive syndromes: septicemia and meningitis. Septicemia is the most common clinical presentation, with a case fatality rate as high as 60% among the elderly. Pneumococcal meningitis has a case-fatality rate of 30%, but may be as high as 80% in elderly persons. Symptoms of meningitis include abrupt onset of high fever, headache, lethargy, vomiting, irritability, and nuchal rigidity. It is the leading cause of bacterial meningitis in children less than 5 years of age. Neurologic sequelae are common among meningitis survivors.

Infectious Agent
*Streptococcus pneumoniae*, a gram-positive diplococcus. Most strains causing severe forms of disease are encapsulated; there are 90 known capsular serotypes.

Reservoir
The nasopharynx of asymptomatic human carriers. Carriage is more common in children than adults.

Transmission
Droplet spread and contact with respiratory secretions.

Incubation
Unknown; probably short, 1-4 days.

Period of Communicability
Period of communicability is unknown, but it is presumed that transmission can occur as long as *S. pneumoniae* occurs in respiratory secretions.

Methods of Control
Conjugate and polysaccharide vaccines are available for the prevention of pneumococcal disease. The conjugate vaccine (PCV7) is approved for children younger than 24 months of age and children 24-59 months of age at risk for invasive disease. PCV7 is administered at 2, 4, 6, and 12-15 months of age. The polysaccharide vaccine (PPV23) is recommended for all adults 65 years of age and older and any
person 2 years of age or older at high risk for invasive pneumococcal disease (chronic
disease such as cardiovascular disease, pulmonary disease or diabetes, and individuals
with cochlear implants).

**Reporting Classification**
Class 2; invasive disease in children less than 5 years of age and all antibiotic resistant
invasive disease.

**Epidemiology and Trends**
In 2010 there were 19 reported cases of invasive disease caused by *S. pneumoniae* in
children less than 5 years of age. This was comparable to the 28 reported cases in 2009
(Figure 35). Of these 19 cases, 12 (63%) manifested as septicemia, 4 (21%) had
meningitis, and three (16%) had *S. pneumoniae* isolated from another sterile site. Ages
ranged from 4 months to 3 years of age. Twelve of the 19 invasive *S. pneumoniae*
cases were antibiotic resistant.

A total of 96 cases of invasive *S. pneumoniae* infections were reported in 2010. Thirty-six
(38%) of those cases were reported as antibiotic resistant, compared to 56 cases
reported in 2009. This total included 12 children less than 5 years of age. Of the 36
reported cases, 27 (75%) were septic, three (8%) had meningitis, and two (6%) had *S.
pneumonia* isolated from pleural fluid. The specimen source for four cases was not
noted. Reported cases of antibiotic resistant invasive *S. pneumonia* disease ranged in
age from 5 months to 78 years, with a median age of 40 years (Figure 36).

**Figure 35**

![Figure 35: *Streptococcus pneumoniae*, Invasive Disease, Children less than 5 Years of Age, by Age Group and Clinical Presentation, Mississippi, 2010](image-url)
Rabies

Clinical Features
Rabies is an acute fatal progressive disease that affects the central nervous system. Early signs include anxiety, discomfort or paresthesia at the site of the bite of an infected animal, primarily raccoons and bats in the U.S. Progression to symptoms of cerebral dysfunction such as confusion, agitation, delirium, hallucinations, and insomnia occurs within a few days of symptom onset. This is followed by generalized paralysis, coma and death within 2 to 10 days.

Infectious Agent
Lyssavirus, family Rhabdoviridae; an RNA virus. Variants occur among animal species and geographic location, but all of the members of the genus are antigenically related.

Reservoir
Rabies has an urban and a wild cycle. The urban cycle (maintained by rabid dogs) has been reduced greatly in the U.S., but carnivores (primarily raccoons, wild canids, and skunks) and several species of insectivorous bats maintain the wild cycle in areas of the U.S. Currently, only bats maintain the cycle in Mississippi.
Transmission
The most common mode of rabies virus transmission is through the bite of an infected host. All mammals are susceptible to varying degrees. Transmission has also been documented through organ transplantation, specifically corneal transplants, from a donor dying of undiagnosed rabies.

Incubation
The incubation period can be up to six months or longer. The incubation period is longer the farther away the bite is from the CNS.

Period of Communicability
Rabies is transmissible once it reaches the CNS and can be found in the salivary glands. The animal is usually exhibiting abnormal behavior and other clinical signs by this time.

Methods of Control
The best method of control is prevention. Domestic animal rabies vaccination programs, as well as pre- and post-exposure rabies vaccination in humans have significantly decreased the human risk and deaths from rabies in the United States. People who are bitten by animals that are known reservoirs of rabies exhibiting abnormal behavior, such as unprovoked aggressiveness, increased drooling or paralysis should be considered at higher risk, and consideration should be given to the use of post-exposure vaccination.

The following is a summary of these guidelines:

- For immune competent individuals receiving first-time rabies post exposure vaccine, the recommended series has been reduced from a series of 5 vaccine
doses administered on days 0, 3, 7, 14, and 28 to a series of 4 vaccine doses administered on days 0, 3, 7, and 14.

- ACIP recommendations for the use of Rabies Immune Globulin (RIG) remain unchanged.
- The number of doses recommended for persons who are immunosuppressed has not changed.

**Reporting Classification**

Class 1 (human or animal).

**Epidemiology and Trends**

In the U.S. in the 1940s and 1950s, canines were the predominant reservoir and cause of human rabies. By 2006, however, approximately 92% of animal rabies cases were in wildlife, and only 8% were in domestic animals. This change is attributed to concerted, targeted rabies vaccination campaigns and stray animal control that have reduced the number of canine rabies cases from 6,947 in 1947 to 69 in 2010. Currently, most human cases in the United States are caused by bat strains of rabies. In the U.S., skunks and bats are now the most commonly reported rabid animal behind raccoons.

The MSDH PHL is the only laboratory in Mississippi that tests for rabies in animals. Since 1962, bats are the only animals that have tested positive for rabies in Mississippi. Usually, between 2 to11 bats test positive each year. There were no positive bats out of 53 tested in the PHL in 2010. Since 2001, there has been a wide geographic distribution of positive bats, with 51 reported positives in 25 counties (Figure 37). There has not been an indigenous terrestrial animal (land) rabies case reported in Mississippi since 1961, however, rabies occurs in terrestrial animals annually in states that border Mississippi (Arkansas, Alabama, Louisiana, and Tennessee).

Mississippi reported a human case of rabies due to a bat strain in a 10 year old boy in 2005. Prior to this 2005 human case, the last reported human rabies case in Mississippi was in 1953 and this was transmitted by a terrestrial animal.
### Rocky Mountain spotted fever

<table>
<thead>
<tr>
<th>Year</th>
<th>Case Total</th>

<td>27</td>
<td>0.9</td>
</tr>
<tr>
<td>2009</td>
<td>9</td>
<td>0.3</td>
</tr>
</tbody>
</table>

#### Clinical Features
A rickettsial illness with acute onset of fever, severe headache, malaise, myalgia, nausea, vomiting, and may include a macular or maculopapular rash on the extremities, including the palms and soles, which usually spreads over the entire body. A petechial rash often follows. In untreated cases and those with delayed recognition, fatality occurs in 13-25% of the cases. Early stages of Rocky Mountain spotted fever (RMSF) are often confused with ehrlichiosis and meningococcemia.

#### Infectious Agent
*Rickettsia rickettsii*, a gram-negative coccobacillus.

#### Reservoir
Small rodents (chipmunks, squirrels, white-footed mice).
Transmission
Through bite of an infected *Dermacentor variabilis* tick (American dog tick). A 4-6 hour attachment is required for transmission.

Incubation
3-14 days (most occurring between 5-7 days).

Period of Communicability
No evidence of person to person transmission.

Methods of Control
Avoid tick infested areas when possible. When unavoidable, use tick repellant and measures to decrease tick exposure. After leaving tick prone areas, examine body well and remove any ticks; removing the embedded head of the tick is not necessary.

Reporting Classification
Class 2.

Epidemiology and Trends
In 2010, there were 27 cases of Rocky Mountain spotted fever reported in Mississippi. This is higher than the three year (2007-2009) average of 14 cases (Figure 38). The cases ranged in age from 19 to 77 years of age. There were no reported deaths.

Rocky Mountain Spotted Fever Rates by Year, United States and Mississippi, 2001-2010

Incidence per 100,000 population
**Clinical Features**
A mild, febrile viral disease characterized by a 3 day maculopapular rash. Children often have few signs or symptoms other than the rash. The rash, typically fainter than a measles rash, appears on the face initially and progresses distally. Adults may have a febrile prodrome and lymphadenopathy. Up to 50% of all rubella infections are subclinical or asymptomatic. Complications occur most often in adults and include arthritis and encephalitis. Infection during pregnancy, especially in the first trimester, may result in congenital rubella syndrome (CRS), causing fetal death, prematurity or birth defects.

**Infectious Agent**
Rubella virus is classified as a togavirus, genus Rub virus.

**Reservoir**
Humans.

**Transmission**
Direct contact with nasopharyngeal secretions of infected persons or by droplet spread. Rubella is moderately contagious. Maternal-fetal transmission causes CRS.

**Incubation**
Usually 14 days, with a range of 12-23 days.

**Period of Communicability**
The period of communicability is about 1 week before and up to 5-7 days after onset of the rash. Infants with congenital rubella syndrome may shed the virus for months after birth.

**Methods of Control**
Vaccination is the most effective method in preventing rubella. Rubella vaccine is available combined with measles and mumps vaccines as MMR. The first dose of MMR is recommended at 12-15 months, followed by a second dose at 4-6 years. All susceptible adolescents and adults, especially women of child bearing age, should be vaccinated with MMR vaccine.
Reporting Classification
Class 2.

Epidemiology and Trends
There were no reported cases of rubella in Mississippi in 2010. The last reported case in the state was in a 4 year old in 1986.

Salmonellosis

<table>

<td>901</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Clinical Features
Salmonellosis is a bacterial disease that commonly presents as acute enterocolitis, with sudden onset of headache, abdominal pain, diarrhea, nausea and sometimes vomiting. Fever is almost always present. Dehydration may occur in infants and the elderly, and septicemia occasionally results from infection.

Infectious Agent
Salmonella organisms are gram negative bacilli. The genus Salmonella is divided into two species: S. enterica (divided into six subspecies) and S. bongori. Subspecies are further divided into multiple serotypes. Almost all of the serotypes pathogenic for humans are in one subspecies of S. enterica. Currently, there are more than 2460 identified Salmonella serotypes. The predominant isolates in Mississippi are Salmonella serotypes Javianna, Mississippi, Newport and Typhimurium.

Reservoir
Domestic and wild animals, including poultry, swine, cattle, and rodents, and many reptiles. Humans are also reservoirs, especially in mild and unrecognized cases. Chronic carriers are prevalent in animals and birds.

Transmission
Salmonella is transmitted through ingestion of organisms in food derived from infected animals or food or water contaminated by feces from an infected animal. Person to person transmission by fecal oral route also occurs. S. serotype Enteritidis can be passed trans-ovarially from infected hens to their eggs and transmission can then occur when eggs are not fully cooked.

Incubation
From 6 to 72 hours, usually about 12-36 hours.
**Period of Communicability**
Throughout the course of infection; extremely variable, several days to several weeks. A temporary carrier state occasionally continues for months, especially in infants.

**Methods of Control**
Transmission of *Salmonella* can be controlled with proper food preparation and sanitary measures for food processing, proper hand hygiene, and clean water supplies. MSDH investigates all possible common source food or waterborne outbreaks. The Public Health Laboratory (PHL) requests isolate submission for molecular subtyping with pulsed-field gel electrophoresis (PFGE). The DNA pattern, or “fingerprint”, is submitted to PulseNet, a national tracking network coordinated by the CDC. This system facilitates early detection of common source outbreaks, even if the affected persons are geographically far apart, often allowing the source to be more rapidly identified.

**Reporting Classification**
Class 2.

**Epidemiology and Trends**
In Mississippi, 1,215 cases of salmonellosis were reported to MSDH in 2010. This marked an increase in the rate and number of reported cases in Mississippi (Figure 39). In 2010, the *Salmonella* serotypes Typhimurium, Newport, Mississippi, Enteritidis and Javiana accounted for over 73% of the isolates seen in Mississippi. An outbreak of *Salmonella montevideo* was identified in August 2010; please refer to the “Events of Public Health Significance” section on page 93.
Infections occur in people of all ages, but there is higher incidence in infants and small children. In 2010, 544 (45%) of the cases were in children less than 5 years of age (Figure 40).

<td>1.8</td>
</tr>
</tbody>
</table>

### Clinical Features

An acute bacterial illness characterized by loose, often bloody stools (dysentery), fever, and nausea with vomiting, cramps and tenesmus. Asymptomatic infections occur. Illness is usually self-limited, lasting an average of 4-7 days; however infection with *Shigella dysenteriae* (*S. dysenteriae*) is often associated with severe illness with a case fatality rate of 20% among hospitalized patients. All age groups are susceptible, with the peak incidence in 1-4 year olds. Children in daycares, persons in institutions, and in facilities where adequate hand washing is difficult to maintain are at high risk for outbreaks of shigellosis.

### Infectious Agent

### Reservoir

Humans are the primary reservoir.

### Transmission

Primarily person to person by direct and indirect fecal oral contact. Infection may also occur after ingestion of contaminated food or water. The infective dose can be as low as 100-200 organisms.

### Incubation

Ranges from 12 hours to 7 days, with an average of 2-4 days.

### Period of Communicability

Until the agent is no longer present in feces. This is usually 4 weeks after cessation of symptoms, but asymptomatic carriers may transmit infection for months or longer.

### Methods of Control

Disease prevention includes promotion of good hand washing, exclusion from work for food handlers or from school or daycare for children until symptom free for at least 24 hours. MSDH performs prompt investigation of common source food or waterborne outbreaks, and investigates all reported infections in children less than 5 years of age.
Reporting Classification
Class 2.

Epidemiology and Trends
There were 60 cases of Shigellosis reported to MSDH during 2010, comparable to 2009 (Figure 41). There have been cyclic increases every 6-8 years since 1992, with a peak of 1,426 cases in 2007 associated with a large outbreak that occurred in the Jackson metropolitan area and along the Gulf Coast. Although Shigellosis is usually a summer month illness with 42% of the cases reported between May and August, cases are reported to MSDH year round (Figure 42). The reported cases ranged in age from 10 months to 90 years, with 53% occurring in children less than 10 years of age (Figure 43).

</tr>
</tbody>
</table>

**Clinical Features**

Syphilis is a bacterial infection that has three stages: primary, secondary, and tertiary. The primary lesion (chancre) is a painless indurated ulcer that develops at the sight of initial infection, usually on the external genitalia. Even without treatment, this lesion resolves in 4-6 weeks. Secondary syphilis may then develop and is characterized by a generalized symmetrical maculopapular rash that often involves the soles and palms. It may be accompanied by generalized lymphadenopathy, fever, malaise, sore throat, headache and arthalgia. Clinical manifestations of secondary syphilis usually resolve without treatment in weeks to months. Tertiary syphilis will develop years later in 15-40% if untreated, primarily as cardiovascular or neurosyphilis, or as skin, bone, visceral or mucosal surface gummas. Latent syphilis, a period of seroreactivity without clinical disease, is classified as early (infection acquired within the preceding year) or late (infection of more than a year’s duration).

Fetal transmission occurs through the placenta in untreated women with early syphilis, resulting in congenital syphilis. Congenital syphilis can lead to abortions, stillbirths or death shortly after birth. An infected infant may be asymptomatic for the first few weeks of life; however, late manifestations may occur resulting in CNS involvement or other conditions such as Hutchinson teeth, saddlenose, periostitis, interstitial keratitis or deafness.

**Infectious Agent**

*Treponema pallidum*, a spirochaete.

**Reservoir**

Humans.
Transmission
Syphilis is transmitted primarily by sexual contact with an infected individual with early syphilis (the first year of infection), especially during primary and secondary syphilis. Transplacental infection of the fetus occurs during the pregnancy of an infected woman, resulting in congenital syphilis. Transmission can also result from a blood transfusion if the donor is in the early stages of infection.

Incubation
The average incubation period for syphilis before clinical manifestations is 3 weeks but ranges from 3 – 90 days.

Period of Communicability
In untreated individuals, communicability can last for up to two years. Syphilis is most communicable during the primary and secondary stages. Maternal-fetal transmission is more likely in early syphilis, but may occur at any stage.

Methods of Control
Mechanical barriers, early detection, and effective treatment of the patient and their partners are effective methods in prevention and control of syphilis. MSDH performs contact investigation and treatment for each reported case of syphilis.

Reporting Classification
Class 1.

Epidemiology and Trends
Mississippi had a decline in primary and secondary (P&S) syphilis from 1997 through 2003, and since then has had an increase in rates. Although primary and secondary (P&S) syphilis rates remained below the national average from 2002 through 2006, in 2010, MS ranked third nationally. In 2010, there were 229 reports of P&S syphilis, more than double the number of cases reported in 2006 (Figure 44).
Districts IX and V had the highest incidence of P&S syphilis (Figure 45). Fifty-four percent of P&S syphilis cases occurred among 20-29 year olds (Figure 46) and 85% of the cases in which race was known were among African Americans (Figure 47).
Over the past ten years, Mississippi has had rates higher than national average for early latent syphilis. Since 2004, there has been an increase in the number of cases, and in 2010, there were 398 cases of early latent syphilis reported (Figure 48).
Early latent syphilis was reported in every district. District V and VIII had the highest case rates in the state (Figure 49).

</table>

*per 100,000 population
Forty-three percent of reported cases were among 20-29 year olds (Figure 50). African Americans are disproportionately affected, accounting for 85% of the cases for which race was known (Figure 51) and had rates that were over twelve times greater than the rate among whites.

**Figure 50**

*Early Latent Syphilis Cases by Age Group, Mississippi, 2010*

**Figure 51**

*Early Latent Syphilis Cases by Race, Mississippi, 2006-2010*
Congenital Syphilis

Mississippi saw a decline in congenital syphilis cases reported from 1995 to 2004 and in 2005 and 2006, there were no cases reported. Congenital syphilis has reemerged since 2007 and there were 9 cases reported in 2010 (Figure 52). During this same time frame, P&S syphilis cases among females doubled (from 35 to 69 cases).

Figure 52

Congenital syphilis was seen in five public health districts, with District VIII reporting the highest rate.

<td>121</td>
<td>4.1</td>
</tr>
</tbody>
</table>

Clinical Features

Pulmonary tuberculosis (TB) is the most common form of active TB disease; but, disease can also be extrapulmonary and involve many organ systems. Symptoms are dependent on the site of infection. Pulmonary TB generally presents with cough (dry and later productive), pleuritic chest pains, hemoptysis, shortness of breath, fever, malaise, weakness, night sweats, and anorexia and weight loss. Latent tuberculosis infection without disease (LTBI) can occur and is asymptomatic.
**Infectious Agent**

*Mycobacterium tuberculosis* complex, an acid-fast bacillus.

**Reservoir**

Primarily humans, rarely primates; in some areas, diseased cattle, badgers, swine and other mammals are infected.

**Transmission**

Exposure to tubercle bacilli in airborne droplet nuclei, 1 to 5 microns in diameter. The risk of infection with the tubercle bacillus is directly related to the degree of exposure.

**Incubation**

A positive TB interferon gamma release assay (IGRA) result or TB skin test conversion, indicating LTBI, occur 2-10 weeks after exposure to active TB disease, if infected. Ten percent of persons with LTBI will develop clinically active disease, with the first 12-24 months after infection constituting the most hazardous period. HIV infection increases the risk and shortens the interval for development of active disease following infection with TB. In children, those under 5 years of age have the highest risk of developing disease.

**Period of Communicability**

The degree of communicability depends on the number of bacilli discharged, virulence of the bacilli, adequacy of ventilation, exposure of bacilli to sun or UV light, and opportunities for aerosolization. Antimicrobial chemotherapy usually eliminates communicability within 2-4 weeks. Young children with primary tuberculosis are generally not infectious. LTBI is not infectious.

**Methods of Control**

Prompt identification, diagnosis, follow-up and treatment of potentially infectious patients with TB disease are necessary to interrupt continued transmission. MSDH performs contact investigations, TB targeted testing in high risk areas and provides treatment for all active and latent TB infections.

**Current Initiatives**

A targeted testing program for the homeless population in Jackson was begun in late 2008. An IGRA test, Quantiferon-Gold, is provided to individuals seeking lodging/use of the homeless shelters in the mid-city area. Annual testing is provided and an identification card is issued and needed to access the shelters’ services. Over 1,000 persons have been tested and issued cards.

A pilot program for selected groups of latent TB patients using once-weekly doses of Isoniazid and Rifapentene (3HP) was started in Hinds County and Public Health Districts II, VIII and IX in July 2010. The treatment period is for 12 weeks and requires direct observation of treatment.
Reporting Classification

Class 1.

Epidemiology and Trends

Mississippi had a consistent decline in TB morbidity from 1989 through 2005. TB rates were below the national average in each of the 2001-2006 reporting periods. However, from a low of 103 cases in 2005 and a high in cases in 2007 (137), reported cases have leveled off during the past several years: 2008 (117), 2009 (121) and 116 in 2010. The MS case rate continued to be above the national average in 2010, as it was in 2007 and 2009 (Figure 53).

</tbody>
</table>

Geographically, TB was reported in every public health district, with the highest incidence noted in Public Health Districts I and V (Figure 54).
Disease occurred across all age groups, with the majority in individuals 40 years old and above (Figure 55). Disease in the African American population routinely accounts for approximately two-thirds of morbidity (Figure 56). TB cases among patients co-infected with HIV have increased since the beginning of the decade (Figure 57).

</tbody>
</table>

Clinical Features

An acute viral disease with primary infection (chickenpox) characterized by a generalized pruritic rash that progresses rapidly from macules to papules to vesicular lesions before crusting. The rash will be seen in various stages of development, usually appears first on the head, and is more highly concentrated on the trunk rather than extremities. Adults may have 1-2 days of fever and discomfort prior to rash onset, but the rash is frequently the first sign of disease in children. Adults may have more severe disease and have a higher incidence of complications (secondary bacterial infections, pneumonia, aseptic meningitis and encephalitis). Herpes zoster is a localized manifestation of latent varicella infection, with incidence increasing with age. Lesions usually follow unilateral dermatomal patterns, but can be widespread or disseminated. Postherpetic neuralgia occurs in up to 15% of zoster patients.

Infectious Agent

Varicella zoster virus, a member of the herpes virus group.

Reservoir

Humans.

Transmission

Person to person transmission by airborne droplet or direct contact with the lesions. Indirect spread can occur through contact with articles freshly soiled by vesicular or respiratory secretions. Maternal-fetal transmission also occurs. Susceptible contacts to localized herpes zoster may develop chickenpox by direct contact with fluid from the lesions, but respiratory transmission can occur in disseminated zoster.

Incubation

The incubation period is 14-16 days with a range of 10-21 days.

Period of Communicability

The period of communicability can be up to 5 days before onset of the rash (usually 2 days) and continues until all lesions are crusted (about 5 days).
Methods of Control
The live attenuated varicella vaccine is effective in preventing chickenpox. Routine vaccination is recommended at 12 months with a second dose at 4-6 years of age. Two doses of vaccine are recommended for all susceptible healthcare workers. The vaccine can also be used to prevent disease, or at least modify severity of illness, in susceptible persons if given within 3 days of exposure to an infected individual.

In 2006, FDA approved herpes zoster vaccine for persons 60 years of age and older. Clinical trials indicate vaccine efficacy of 64%, with less severe disease in those who developed zoster, and 66% less postherpetic neuralgia.

MSDH investigates outbreaks of varicella and vaccine is recommended after exposure if there is no evidence of prior disease or vaccination. The vaccine is 70% - 100% effective in preventing or attenuating disease if given within 72 hours of exposure.

Reporting Classification
Class 1: varicella infection, primary, in patients >15 years of age.

Epidemiology and Trends
In 2010, there were 12 reported cases of varicella infection in patients 15 years of age or older. The cases ranged in age from 16 to 43 years. Nine of these 12 cases were epidemiologically linked to two separate outbreaks. The three year average from 2007 to 2009 was 7 cases of varicella per year.

MSDH investigated two varicella outbreaks reported in 2010. Please refer to the “Events of Public Health Significance” section on page 93.

Vibrio disease

<table>
<thead>
<tr>

<td>8</td>
<td>0.3</td>
<td></td>
</tr>
<tr>
<td>2009</td>
<td>11</td>
<td>0.4</td>
<td></td>
</tr>
</tbody>
</table>

Clinical Features
Several noncholera Vibrio species can cause illness in humans, usually wound infections, septicemia or gastroenteritis. Vibrio vulnificus and Vibrio parahaemolyticus are the two most frequently reported species in Mississippi.

V. vulnificus causes sepsis 12 hours to 3 days after ingestion of contaminated seafood, usually raw oysters, especially among people with chronic liver disease, alcoholism, or immunosuppression. These same groups are at risk for severe wound infections from contact with coastal waters. V. vulnificus sepsis is characterized by fever, chills,
blistering skin lesions, shock and death. The case fatality rate is over 50% when septicemia occurs.

V. *parahaemolyticus* infection typically causes gastroenteritis with watery diarrhea with abdominal cramps, nausea, vomiting and fever; less commonly wound infections.

**Infectious Agent**
Anaerobic, gram-negative halophilic (salt requiring) bacteria found naturally in marine and estuarine environments. *Vibrio vulnificus* and *Vibrio parahaemolyticus* are the two most frequently reported species in Mississippi. Other species common to Mississippi are *V. mimics*, *V. holiday*, and *V. fluvialis*. Nontoxigenic *Vibrio cholerae* serogroups (non-O1/non-O139) are also reported.

**Reservoir**
Found free living in warm coastal waters, and in fish and shellfish, particularly oysters.

**Transmission**
Ingestion of the organisms in raw, undercooked, or contaminated fish and shellfish, or any food or water contaminated with raw seafood. Wound infections with *V. vulnificus* occur when wounds are exposed to estuarine waters.

**Incubation**
Median incubation period of 23 hours, with a range of 5-92 hours.

**Period of Communicability**
Not typically transmitted person to person.

**Methods of Control**
Seafood should be cooked adequately. Wounds exposed to seawater (either occupational or accidental) should be rinsed with clean fresh water. All children and immunocompromised individuals, especially alcoholics or individuals with liver disease, should avoid eating raw seafood, especially oysters. MSDH investigates all reported cases to determine the source of infection and possible risk factors of the case.

**Reporting Classification**
Class 2.

**Epidemiology and Trends**
In 2010, there were eight reported *Vibrio* infections. This was a slight decrease from the number of reported cases in 2009 (11) and comparable to the three year average of 9 cases for 2007-2009 (Figure 58).
Of the eight reported cases, three were due to *V. vulnificus* (all isolated from blood cultures), three were due to *V. parahaemolyticus* (two isolated from a stool culture and the other from a wound), and two were due to *V. mimicus* (one isolated from stool cultures and one isolated from a urine culture). There was one reported death attributed to *V. vulnificus* in 2010, in a 79 year old man with an underlying history of cirrhosis.

*Figure 58*
Events of Public Health Significance

This section of the Annual Summary of Selected Reportable Diseases reports on events of public significance, including significant outbreak investigations conducted by the Mississippi State Department of Health (MSDH).

**Botulism Case**

On April 15, 2010, the Mississippi State Department of Health (MSDH) Office of Epidemiology received a telephone call from a Mississippi hospital requesting information on *Clostridium botulinum* toxin testing on a 70 year old female with an underlying history of multiple medical problems. She was admitted to the hospital through the emergency department on April 10, 2010 with a one day history of slurred speech, confusion, dizziness and lower abdominal discomfort. By April 13, 2010 she developed full cranial nerve deficits with paralysis of the eye muscles, facial paralysis, and upper extremity weakness, but retained some strength in her lower extremities. She ultimately went into respiratory failure requiring ventilation. Based on her clinical presentation of descending flaccid paralysis, the local physician notified MSDH to facilitate *Clostridium botulinum* toxin testing. The Centers for Disease Control and Prevention (CDC) was contacted for consultation regarding the potential testing of clinical samples and release of botulinum antitoxin. The local physician was put into contact with the CDC Botulism Office to discuss the patient’s condition and treatment.

The District Health Officer and District Epidemiology staff were contacted to begin the investigation. At the time, the patient was unable to give a food or exposure history. District staff was able to locate and interview several family members. With the help of family members, the District Epidemiology Nurse was able to obtain access to the patient’s home to look for evidence of any foods posing a risk for botulism. The nurse was quickly able to identify an opened jar of home canned beets on the kitchen counter establishing a potential link to botulinum intoxication.

Both the CDC Botulism Officer and the local physician were informed of the discovery. Within four hours of the initial call to MSDH, approval for the release of antitoxin was obtained, and the infusion of antitoxin was begun within 11 hours of first notification.

Prior to the antitoxin infusion, serum and gastric content specimens were collected, and along with the home canned beets, were sent to CDC for evaluation. Testing there confirmed the presence *Clostridium botulinum* toxin type B in the canned beets and in the serum sample. The District staff determined that the canned beets were given to the patient by an elderly neighbor. The patient was given the beets two days prior to the onset of her symptoms. A home visit to the neighbor determined that the neighbor had canned beets and other vegetables that had been given to the neighbor’s son and to the patient. All had been consumed previously with the exception of two
additional jars of beets discovered under the neighbor’s sink. These jars were disposed of by MSDH.

The patient initially improved after the antitoxin infusion, but again developed respiratory distress, likely due to aspiration, and required re-intubation and ventilation. She was ultimately transferred to a restorative care facility on April 27, and is now undergoing rehabilitation.

**Brucellosis Cases**

There were two reported cases of brucellosis in Mississippi in 2010. Until 2010, the last reported human cases of brucellosis in MS were in 2003.

In 2010 MSDH investigated a case of brucellosis that occurred in a 44 year old man. On June 11, 2010, the MSDH Public Health Laboratory confirmed a *Brucella* species on an isolate submitted from a hospital laboratory. Further testing at the Centers for Disease Control and Prevention (CDC) identified the *Brucella* species as *Brucella suis*. The culture was from a knee aspirate obtained during arthrocentesis on June 2. The patient had undergone arthroscopic surgery in April to repair a right knee meniscus tear from an injury playing basketball. Twice during the month of May, he sought medical attention to have fluid drawn from his knee. On June 2, he presented complaining of “fever” in his knee and had an arthrocentesis and cultures of the fluid grew *Brucella*.

On June 11, a personal interview with the patient was conducted in order to obtain a history of his illness and to identify a possible source of infection. He gave no history of unpasteurized milk consumption. He did hunt and wrestle feral hogs and prepare the hogs for processing. The exposure to feral hog tissue was considered a possible source of infection. The patient was treated and recovered.

The MSDH also investigated the possible risk of exposure to *Brucella* in laboratory employees that handled specimens or isolates. Consultation and guidelines published by the CDC, *Brucellosis: Description, Testing, Treatment, and Laboratory Risk Assessment with Post-exposure Prophylaxis Recommendations for Exposure to Brucella spp.*, ([http://www.cdc.gov/nczved/divisions/dfbmd/diseases/brucellosis/recommendations.html](http://www.cdc.gov/nczved/divisions/dfbmd/diseases/brucellosis/recommendations.html)) were referenced to identify, treat and monitor exposed persons. Possible exposure occurred when biosafety recommendations were not used in the manipulation of isolates. Plates were read and manipulated on an open bench (not under a hood).

With the assistance of the hospital laboratory director and the infection preventionist, twenty-eight laboratory personnel were identified as having potential exposure to the bacteria. Three were identified with high risk exposure and twenty-five with low risk exposure. All were offered post-exposure prophylaxis (PEP) with doxycycline and
rifampin and serological testing for \textit{Brucella} at 0, 2 weeks, 4 weeks, 6 weeks, and 24 weeks post-exposure. All individuals exposed to \textit{Brucella} isolates were to be actively monitored for the development of symptoms weekly for six months after exposure. One high risk laboratorian initiated PEP but stopped after two weeks of treatment due to side effects. Sixteen potentially exposed laboratory personnel initiated blood testing. Fifteen had three or more tests during the six month period. Seven had all five tests. All were assessed for symptoms on a weekly basis.

On October 18, 2010, the MSDH was notified by the infection preventionist that a high risk laboratory employee was reporting intermittent fever, malaise, and body aches. This employee’s identified exposure was the reading and manipulation of the isolates on the open bench. She had declined post-exposure prophylaxis when offered. She had had regular, on time serum samples for serology that were negative. The last one was on 8/17 and the final test was due on 11/28. A sample for serology was obtained as well as blood cultures. The employee was started on treatment with doxycycline and rifampin. The employee’s serology was greatly elevated and the blood culture grew \textit{B. suis}.

The MSDH identified another possible exposure from the handling of the blood culture specimen obtained on the symptomatic laboratory employee. The laboratory had been instructed to obtain the blood culture but not to plate the culture. A part-time night employee was not aware of this and plated the culture. She was considered to have had a high risk exposure and was offered testing and post-exposure prophylaxis. She completed PEP, all serological testing was negative and she developed no symptoms after 6 months. Two other employees were identified as low risk for exposure. One declined all recommended follow-up. One declined PEP but had three serology tests performed that were negative. Both low-risk employees were symptom free at six months.

\textbf{Legionella Outbreak}

In June, 2010, the MSDH was made aware of a \textit{Legionella} case potentially associated with a hotel stay. An environmental inspection was conducted. In July, 2010, the MSDH was notified of two out-of-state residents who had been diagnosed with Legionnaires’ disease that had traveled to Mississippi prior to their onset and stayed at the same hotel as the initial case. The MSDH in conjunction with the CDC began a full scale epidemiological and environmental investigation. Sixty environmental samples were collected for culture. 295 interviews were conducted of hotel guests. A total of eight \textit{Legionnaire’s} cases, 5 from MS and 3 out-of-state, were identified, including one death. Cases ranged from 31 to 61 years of age with the median age being 57 years. Environmental sampling yielded six positive cultures for two separate strains of \textit{Legionella} from the cooling tower of the hotel. Additional monoclonal antibody (Mab) testing and sequence based typing (SbT) of the clinical and environmental samples
found the clinical isolates to be identical to one of the two isolates obtained from the cooling tower. The MSDH and CDC recommended remediation of the cooling system be conducted in accordance with the American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) Guideline 12-2000, *Minimizing the Risk of Legionellosis Associated with Building Water Systems*. Follow-up testing at the facility is ongoing.

**Norovirus Outbreak**

Norovirus has been implicated as the most common cause of outbreaks of nonbacterial gastroenteritis. Infection typically results in a self-limited, mild to moderate illness, lasting one to two days in most individuals, with clinical symptoms of nausea, vomiting, diarrhea, abdominal pain and low grade fever. Transmission is through the fecal-oral route, and outbreaks are common in closed group settings such as nursing homes, hospitals, and ships. The virus is persistent in the environment and can be transmitted person-to-person via either direct contact or contact with contaminated inanimate objects, such as doorknobs. Almost any type of food that is contaminated may serve as a vehicle for outbreaks. The incubation period is usually 24-48 hours after exposure. Individual cases of norovirus infection are not reportable in Mississippi, but any suspected outbreak is reportable as Class 1.

The Mississippi State Department of Health (MSDH) investigated a report of gastrointestinal illness in several individuals who attended a conference held March 8-12, 2010 in Mississippi. Eleven individuals were identified with an illness consistent with norovirus infection, which was confirmed as norovirus genogroup GII by RT-PCR testing in two persons. The investigation epidemiologically linked the illnesses to the consumption of raw oysters harvested in Louisiana. Leftover oysters served at the conference were obtained and sent to the FDA Gulf Coast Seafood Laboratory (GCSL) in Dauphin Island, Alabama where they were found positive for norovirus GII.

Oysters are filter feeders and can efficiently concentrate viruses and bacteria from contaminated water. Oysters have previously been implicated in the transmission of norovirus gastroenteritis in Mississippi. In January 2009, and again in March 2009, norovirus outbreaks were epidemiologically linked to the consumption of raw oysters harvested near Pass Christian, Mississippi, resulting in the closure of that harvest area for the remainder of the 2009 season.

The noroviruses isolated in the stool samples in the outbreak reported in 2010 were two separate genotypes. Mixed outbreaks can occur and are usually explained by non-point source contamination, such as sewage runoff. As a result of this investigation, the Louisiana Department of Health closed the identified harvest area.
**Salmonella Outbreak**

In 2010 MSDH investigated a large outbreak of *Salmonella montevideo* in a restaurant. On August 8, 2010, MSDH was notified by an Emergency Department of multiple persons who were presenting with complaints of vomiting and diarrhea. History obtained by the Emergency Department staff identified the restaurant as being a common exposure.

A complete epidemiological and environmental inspection was conducted. Sixteen cases were culture confirmed for *Salmonella montevideo*. Twelve additional cases were epidemiologically linked to the restaurant. Environmental specimens were taken and were also positive for *Salmonella montevideo*. Ill foodhandlers and improper handling of food were identified as the most likely source of this outbreak.

**Varicella Outbreak #1**

This outbreak occurred May 24-June 10, 2010. The illness was characterized by a generalized itchy rash and fever among inmates and staff at a correctional facility. A clinical sample was obtained by MSDH staff. This sample was confirmed positive by PCR for varicella virus by the MSDH Public Health Laboratory. All inmates in the correctional facility pod where the first case was found were quarantined. All inmates in the facility (329) and the correctional facility staff were assessed and monitored for symptoms. Three inmates and 2 staff met the case definition for varicella. Recommendations were made to facilitate the interruption of person to person spread. Post exposure varicella vaccine was offered by the correctional facility to the inmates and employees. Daily contact was maintained between the correctional facility and the Health Department nurse.

**Varicella Outbreak #2**

This outbreak was reported on December 17, 2010 by a residential facility. The illness was characterized by an itchy rash and fever in a resident at the facility. A clinical sample was collected by MSDH staff. This sample was confirmed positive by PCR for varicella virus by the MSDH Public Health Laboratory. Post exposure vaccination was recommended for susceptible staff and residents. Recommendations were made to facilitate the interruption of person to person spread. The facility obtained disease and/or vaccine history for 147 employees. 116 susceptible residents received varicella vaccine. Three residents and no staff members met the case definition for varicella.
